FEATURES

High accuracy
- 0.02% maximum nonlinearity, 0 V to 2 V rms input
- 0.10% additional error to crest factor of 3

Wide bandwidth
- 8 MHz at 2 V rms input
- 600 kHz at 100 mV rms

Computes
- True rms
- Square
- Mean square
- Absolute value

dB output (60 dB range)

Chip select/power-down feature allows
- Analog three-state operation
- Quiescent current reduction from 2.2 mA to 350 μA

14-lead SBDIP, 14-lead low cost CERDIP, and 16-lead SOIC_W

GENERAL DESCRIPTION

The AD637 is a complete, high accuracy, monolithic rms-to-dc converter that computes the true rms value of any complex waveform. It offers performance that is unprecedented in integrated circuit rms-to-dc converters and comparable to discrete and modular techniques in accuracy, bandwidth, and dynamic range. A crest factor compensation scheme in the AD637 permits measurements of signals with crest factors of up to 10 with less than 1% additional error. The wide bandwidth of the AD637 permits the measurement of signals up to 600 kHz with inputs of 200 mV rms and up to 8 MHz when the input levels are above 1 V rms.

As with previous monolithic rms converters from Analog Devices, Inc., the AD637 has an auxiliary dB output available to users. The logarithm of the rms output signal is brought out to a separate pin, allowing direct dB measurement with a useful range of 60 dB. An externally programmed reference current allows the user to select the 0 dB reference voltage to correspond to any level between 0.1 V and 2.0 V rms.

A chip select connection on the AD637 permits the user to decrease the supply current from 2.2 mA to 350 μA during periods when the rms function is not in use. This feature facilitates the addition of precision rms measurement to remote or handheld applications where minimum power consumption is critical. In addition, when the AD637 is powered down, the output goes to a high impedance state. This allows several AD637s to be tied together to form a wideband true rms multiplexer.

The input circuitry of the AD637 is protected from overload voltages in excess of the supply levels. The inputs are not damaged by input signals if the supply voltages are lost.

The AD637 is available in accuracy Grade J and Grade K for commercial temperature range (0°C to 70°C) applications, accuracy Grade A and Grade B for industrial range (−40°C to +85°C) applications, and accuracy Grade S rated over the −55°C to +125°C temperature range. All versions are available in hermetically sealed, 14-lead SBDIP, 14-lead CERDIP, and 16-lead SOIC_W packages.

The AD637 computes the true root mean square, mean square, or absolute value of any complex ac (or ac plus dc) input waveform and gives an equivalent dc output voltage. The true rms value of a waveform is more useful than an average rectified signal because it relates directly to the power of the signal. The rms value of a statistical signal is also related to the standard deviation of the signal.

The AD637 is laser wafer trimmed to achieve rated performance without external trimming. The only external component required is a capacitor that sets the averaging time period. The value of this capacitor also determines low frequency accuracy, ripple level, and settling time.

The on-chip buffer amplifier can be used either as an input buffer or in an active filter configuration. The filter can be used to reduce the amount of ac ripple, thereby increasing accuracy.

  - Max: 350 μA

---

1 Specifications shown in **bold** are tested on all production units at final electrical test. Results from those tests are used to calculate outgoing quality levels. All minimum and maximum specifications are guaranteed, although only those shown in boldface are tested on all production units.

2 Accuracy specified 0 V rms to 7 V rms dc with AD637 connected, as shown in Figure 5.

3 Nonlinearity is defined as the maximum deviation from the straight line connecting the readings at 10 mV and 2 V.

4 Error vs. crest factor is specified as additional error for 1 V rms.

5 Input voltages are expressed in volts rms. Percent is in % of reading.

6 With external 2 kΩ pull-down resistor tied to −V<sub>i</sub>.

Stresses above those listed under Absolute Maximum Ratings may cause permanent damage to the device. This is a stress rating only; functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

ESD CAUTION

ESD (electrostatic discharge) sensitive device. Charged devices and circuit boards can discharge without detection. Although this product features patented or proprietary protection circuitry, damage may occur on devices subjected to high energy ESD. Therefore, proper ESD precautions should be taken to avoid performance degradation or loss of functionality.

</table>
The AD637 embodies an implicit solution of the rms equation that overcomes the inherent limitations of straightforward rms computation. The actual computation performed by the AD637 follows the equation

\[ V_{rms} = \text{Avg} \left( \frac{V_{IN}^2}{V_{rms}} \right) \]

Figure 4 is a simplified schematic of the AD637, subdivided into four major sections: absolute value circuit (active rectifier), squarer/divider, filter circuit, and buffer amplifier. The input voltage (Vin), which can be ac or dc, is converted to a unipolar current I1 by the active rectifiers A1 and A2. I1 drives one input of the squarer/divider, which has the transfer function

\[ I_i = \frac{I_i^2}{I_3} \]

The output current of the squarer/divider Ii drives A4, forming a low-pass filter with the external averaging capacitor. If the RC time constant of the filter is much greater than the longest period of the input signal, then the A4 output is proportional to the average of Ii. The output of this filter amplifier is used by A3 to provide the denominator current I3, which equals Avg I4 and is returned to the squarer/divider to complete the implicit rms computation

\[ I_i = \text{Avg} \left( \frac{I_i^2}{I_3} \right) = I_i \text{ rms} \]

and

\[ V_{OUT} = V_{IN} \text{ rms} \]

To compute the absolute value of the input signal, the averaging capacitor is omitted. However, a small capacitance value at the averaging capacitor pin is recommended to maintain stability; 5 pF is sufficient for this purpose. The circuit operates identically to that of the rms configuration, except that I3 is now equal to Ii, giving

\[ I_i = \frac{I_i^2}{I_i} \]

\[ I_i = |I_i| \]

The denominator current can also be supplied externally by providing a reference voltage (VREF) to Pin 6. The circuit operates identically to the rms case, except that I3 is now proportional to VREF. Therefore,

\[ I_i = \text{Avg} \left( \frac{I_i^2}{I_3} \right) \]

and

\[ V_{OUT} = \frac{V_{IN}^2}{V_{DEN}} \]

This is the mean square of the input signal.
STANDARD CONNECTION

The AD637 is simple to connect for a majority of rms measurements. In the standard rms connection shown in Figure 5, only a single external capacitor is required to set the averaging time constant. In this configuration, the AD637 computes the true rms of any input signal. An averaging error, the magnitude of which is dependent on the value of the averaging capacitor, is present at low frequencies. For example, if the filter capacitor, $C_{AV}$, is 4 μF, the error is 0.1% at 10 Hz and increases to 1% at 3 Hz. To measure ac signals, the AD637 can be ac-coupled by adding a nonpolar capacitor in series with the input, as shown in Figure 5.

The performance of the AD637 is tolerant of minor variations in the power supply voltages; however, if the supplies used exhibit a considerable amount of high frequency ripple, it is advisable to bypass both supplies to ground through a 0.1 μF ceramic disc capacitor placed as close to the device as possible.

The output signal range of the AD637 is a function of the supply voltages, as shown in Figure 6. The output signal can be used buffered or nonbuffered, depending on the characteristics of the load. If no buffer is needed, tie the buffer input (Pin 1) to common. The output of the AD637 is capable of driving 5 mA into a 2 kΩ load without degrading the accuracy of the device.

CHIP SELECT

The AD637 includes a chip select feature that allows the user to decrease the quiescent current of the device from 2.2 mA to 350 μA. This is done by driving CS, Pin 5, to below 0.2 V dc. Under these conditions, the output goes into a high impedance state. In addition to reducing the power consumption, the outputs of multiple devices can be connected in parallel to form a wide bandwidth rms multiplexer. Tie Pin 5 high to disable the chip select.

OPTIONAL TRIMS FOR HIGH ACCURACY

The AD637 includes provisions for trimming out output offset and scale factor errors resulting in significant reduction in the maximum total error, as shown in Figure 7. The residual error is due to a nontrimmable input offset in the absolute value circuit and the irreducible nonlinearity of the device.

Referring to Figure 8, the trimming process is as follows:

- Offset trim: Ground the input signal ($V_{IN}$) and adjust R1 to give 0 V output from Pin 9. Alternatively, R1 can be adjusted to give the correct output with the lowest expected value of $V_{IN}$.

- Scale factor trim: Resistor R4 is inserted in series with the input to lower the range of the scale factor. Connect the desired full-scale input to $V_{DS}$, using either a dc or a calibrated ac signal, and trim Resistor R3 to give the correct output at Pin 9 (that is, 1 V dc at the input results in a dc output voltage of 1000 V dc). A 2 V p-p sine wave input yields 0.707 V dc at the output. Remaining errors are due to the nonlinearity.
CHOOSING THE AVERAGING TIME CONSTANT

The AD637 computes the true rms value of both dc and ac input signals. At dc, the output tracks the absolute value of the input exactly; with ac signals, the AD637 output approaches the true rms value of the input. The deviation from the ideal rms value is due to an averaging error. The averaging error comprises an ac component and a dc component. Both components are functions of input signal frequency $f$ and the averaging time constant $\tau$ ($\tau$: $25 \text{ ms}/\mu\text{F}$ of averaging capacitance). Figure 9 shows that the averaging error is defined as the peak value of the ac component (ripple) and the value of the dc error.

The peak value of the ac ripple component of the averaging error is defined approximately by the relationship

$$\frac{50}{6.3} \tau f \text{ in } \% \text{ of reading where } (\tau > 1/f)$$

The ac ripple component of averaging error is greatly reduced by increasing the value of the averaging capacitor. There are two major disadvantages to this: the value of the averaging capacitor becomes extremely large and the settling time of the AD637 increases in direct proportion to the value of the averaging capacitor ($T_s = 115 \text{ ms}/\mu\text{F}$ of averaging capacitance). A preferable method of reducing the ripple is by using the postfilter network, as shown in Figure 11. This network can be used in either a 1-pole or 2-pole configuration. For most applications, the 1-pole filter gives the best overall compromise between ripple and settling time.
Figure 11. 2-Pole Sallen-Key Filter

Figure 12 shows values of CAV and the corresponding averaging error as a function of sine wave frequency for the standard rms connection. The 1% settling time is shown on the right side of Figure 12.

Figure 13 shows the relationship between the averaging error, signal frequency settling time, and averaging capacitor value. Figure 13 is drawn for filter capacitor values of 3.3 times the averaging capacitor value. This ratio sets the magnitude of the ac and dc errors equal at 50 Hz. As an example, by using a 1 μF averaging capacitor and a 3.3 μF filter capacitor, the ripple for a 60 Hz input signal is reduced from 5.3% of the reading using the averaging capacitor alone to 0.15% using the 1-pole filter. This gives a factor of 30 reduction in ripple, and yet the settling time only increases by a factor of 3. The values of filter capacitor CAV and filter capacitor C2 can be calculated for the desired value of averaging error and settling time by using Figure 13.

The symmetry of the input signal also has an effect on the magnitude of the averaging error. Table 5 gives the practical component values for various types of 60 Hz input signals. These capacitor values can be directly scaled for frequencies other than 60 Hz—that is, for 30 Hz, these values are doubled, and for 120 Hz they are halved.

For applications that are extremely sensitive to ripple, the 2-pole configuration is suggested. This configuration minimizes capacitor values and the settling time while maximizing performance.

Figure 14 can be used to determine the required value of CAV, C2, and C3 for the desired level of ripple and settling time.

**FREQUENCY RESPONSE**

The frequency response of the AD637 at various signal levels is shown in Figure 15. The dashed lines show the upper frequency limits for 1%, 10%, and ±3 dB of additional error. For example, note that for 1% additional error with a 2 V rms input, the highest frequency allowable is 200 kHz. A 200 mV signal can be measured with 1% error at signal frequencies up to 100 kHz.

To take full advantage of the wide bandwidth of the AD637, care must be taken in the selection of the input buffer amplifier. To ensure that the input signal is accurately presented to the converter, the input buffer must have a −3 dB bandwidth that is wider than that of the AD637. Note the importance of slew rate in this application. For example, the minimum slew rate required for a 1 V rms, 5 MHz, sine wave input signal is 44 V/μs. The user is cautioned that this is the minimum rising or falling slew rate and that care must be exercised in the selection of the buffer amplifier, because some amplifiers exhibit a two-to-one difference between rising and falling slew rates. The AD845 is recommended as a precision input buffer.

AC MEASUREMENT ACCURACY AND CREST FACTOR

Crest factor is often overlooked in determining the accuracy of an ac measurement. Crest factor is defined as the ratio of the peak signal amplitude to the rms value of the signal (CF = Vp/V rms).

Most common waveforms, such as sine and triangle waves, have relatively low crest factors (≤2). Waveforms that resemble low duty cycle pulse trains, such as those occurring in switching power supplies and SCR circuits, have high crest factors. For example, a rectangular pulse train with a 1% duty cycle has a crest factor of 10 (CF = 10√D).

CONNECTION FOR dB OUTPUT

Another feature of the AD637 is the logarithmic, or decibel, output. The internal circuit that computes dB works well over a 60 dB range. Figure 20 shows the dB measurement connection. The user selects the 0 dB level by setting R1 for the proper 0 dB reference current, which is set to cancel the log output current from the squarer/divider circuit at the desired 0 dB point. The external op amp is used to provide a more convenient scale and to allow compensation of the +0.3%/°C temperature drift of the dB circuit. The temperature resistor R3, as shown in Figure 20, is available from Precision Resistor Co., Inc., in Largo, Fla. (Model PT146). Consult its website for additional information.
dB CALIBRATION

Refer to Figure 20:

- Set $V_{IN} = 1.00 \text{ V dc or } 1.00 \text{ V rms}$
- Adjust R1 for 0 dB out = 0.00 V
- Set $V_{IN} = 0.1 \text{ V dc or } 0.10 \text{ V rms}$
- Adjust R2 for dB out = $-2.00 \text{ V}$

Any other dB reference can be used by setting $V_{IN}$ and R1 accordingly.

LOW FREQUENCY MEASUREMENTS

If the frequencies of the signals to be measured are below 10 Hz, the value of the averaging capacitor required to deliver even 1% averaging error in the standard rms connection becomes extremely large. Figure 21 shows an alternative method of obtaining low frequency rms measurements. The averaging time constant is determined by the product of \( R \) and \( C_{AV1} \), in this circuit, 0.5 sec/\( \mu \)F of \( C_{AV} \). This circuit permits a 20:1 reduction in the value of the averaging capacitor, permitting the use of high quality tantalum capacitors. It is suggested that the 2-pole, Sallen-Key filter shown in Figure 21 be used to obtain a low ripple level and minimize the value of the averaging capacitor.

If the frequency of interest is below 1 Hz, or if the value of the averaging capacitor is still too large, the 20:1 ratio can be increased. This is accomplished by increasing the value of \( R \). If this is done, it is suggested that a low input current, low offset voltage amplifier, such as the AD548, be used instead of the internal buffer amplifier. This is necessary to minimize the offset error introduced by the combination of amplifier input currents and the larger resistance.

VECTOR SUMMATION

Vector summation can be accomplished through the use of two AD637s, as shown in Figure 22. Here, the averaging capacitors are omitted (nominal 100 pF capacitors are used to ensure stability of the filter amplifier), and the outputs are summed as shown. The output of the circuit is

\[
V_{OUT} = \sqrt{V_X^2 + V_Y^2}
\]

This concept can be expanded to include additional terms by feeding the signal from Pin 9 of each additional AD637 through a 10 k\( \Omega \) resistor to the summing junction of the AD711 and tying all of the denominator inputs (Pin 6) together.

If \( C_{AV} \) is added to IC1 in this configuration, then the output is

\[
\sqrt{V_X^2 + V_Y^2}
\]

If the averaging capacitor is included on both IC1 and IC2, the output is

\[
\sqrt{V_X^2 + V_Y^2}
\]

This circuit has a dynamic range of 10 V to 10 mV and is limited only by the 0.5 mV offset voltage of the AD637. The useful bandwidth is 100 kHz.
Figure 22. Vector Sum Configuration

\[ V_{OUT} = \sqrt{V_{x2}^2 + V_{y2}^2} \]
EVALUATION BOARD

Figure 23 shows a digital image of the AD637-EVALZ, an evaluation board specially designed for the AD637. It is available at www.analog.com and is fully tested and ready for bench testing after connecting power and signal I/O. The circuit is configured for dual power supplies, and standard BNC connectors serve as the signal input and output ports.

Referring to the schematic in Figure 30, the input connector RMS_IN is capacitively coupled to Pin 15 (V_{in} of SOIC package) of the AD637. The DC_OUT connector is connected to Pin 11, RMS_OUT, with provisions for connections to the output buffer between Pin 1 and Pin 16. The buffer is an uncommitted op amp, and is configured on the AD637-EVALZ as a low-pass Sallen-Key filter whose \( f_c < 0.5 \text{ Hz} \). Users can connect to the buffer by moving the FILTER switch to the on position. DC_OUT is still the output of the AD637, and the test loop, BUF_OUT, is the output of the buffer. The R2 trimmer adjusts the output offset voltage.

The LPF frequency is changed by changing the component values of CF1, CF2, R4, and R5. See Figure 24 and Figure 30 to locate these components. Note that a wide range of capacitor and resistor values can be used with the AD637 buffer amplifier.
